Emily Keddell

Substantiation Decision-Making and Risk Prediction in Child Protection Systems

In the last few years, predictive risk modelling has been suggested for use in the child welfare environment as an efficient means of targeting preventive resources and improving practitioner decision-making. First raised in the green paper on vulnerable children, then translated into the white paper on vulnerable children and the Children’s Action Plan, and now part of the Child, Youth and Family review remit, this particular tool has provoked a barrage of opinions and wide-ranging analyses, concerning ethical implications, feasibility and data issues, possible uses and political consequences (Ministry of Social Development, 2011, 2012). This has resulted in a flurry of media, academic and policy debates, both here and internationally, and many reviews and related publications (Dare, 2013; Fluke and Wulczyn, 2013; Oakley, 2013; Blank et al., 2013; Keddell, 2015a, 2015b; Oak, 2015; Gillingham, 2015; de Haan and Connolly, 2014; Ministry of Social Development, 2014a; Pierse, 2014; Shlonsky, n.d.). While there are many aspects of the tool that require debate and analysis, this article focuses on one: its use of substantiation data as the outcome variable it attempts

Emily Keddell is a Senior Lecturer in Social Work at the University of Otago.
to predict. Substantiation decisions are discussed in the light of the international literature, with some comment on the implications for child welfare system design. As the substantiation decision is variable, and the population available to be substantiated is skewed and heterogeneous, there are considerable challenges to using substantiation as a proxy for child abuse incidence across the population. This challenges its use for prediction at the individual level. However, the research this article draws on highlights the need for policy directions that address needs and risks across the macro, community and family levels; and the need for more research on the causes of decision-making variability in the child welfare context.

**Big data and ‘carving out’ the targets of social policy**

The use of big data in social life is steadily growing. From the selection of professional sportspersons to the shaping of outcomes in schools and universities, the use of data derived from administrative and other everyday sources is positioned as a source of important secrets, and reflects a ‘profound faith’ in the objectivity assumed to accompany it (Beer, 2015). Amoore and Piotukh (2015) argue that in an age of big data the use of algorithms to cut out particular slices or combinations of the data is not only descriptive, it is constitutive of social life: decisions, meanings and truths are generated in such a way as to promote certain ideas about society and individuals, while leaving others invisible. Indeed, Amoore and Piotukh (2015, p.4) argue that

an image of interest is extracted from a whole, data analytics are instruments of perception: they carve out images; reduce heterogeneous objects to a homogeneous space; and stitch together qualitatively different things such that attributes can be rendered quantifiable. (Amoore and Piotukh, 2015, p.4).

In this manner, the technologies of data analytics are increasingly powerful mediators, and even governors, of social and political life, yet their assumed objectivity is always a view of life, one shaped by the choices of data types, algorithm functions and accompanying narrative logics.

Predictive risk modelling is an example of the use of big data to ‘carve out’ images of risk in a specific way that have a number of implications for policy and practice. What is driving this particular image, what heterogeneities are being homogenised, and what slippages are occurring in this process? What is foregrounded and what is invisible in this particular slice of the data pie? How does the result influence perceptions of child abuse and policy responses to it?

**Why try to predict?**

Predictive modelling is proposed as a way to risk-scale the population with regard to child abuse, with a view to understanding and providing better preventive services, an elusive goal of child protection systems across the Western world. Increasing notifications to formal services threaten to swamp stretched existing systems in most anglophone countries (Spratt, 2012; Lonne, Harries and Lantz, 2013). In this context, understanding who is most at risk of notification and resulting legal interventions is an important issue. For example, Spratt (2012) considers that the impact of multiple adverse events on the population referred to child protection services is crucial to understanding how to target preventive resources effectively. Here in New Zealand, prediction has been attempted via the collection and integration of data sets from multiple administrative sources. Developed via the use of algorithms to identify particular risk factors for a specific outcome, then using that information to identify others prospectively, predictive modelling is seen as having potential as a method of predicting the people for whom the co-occurrence of specific combinations of administrative risk factors puts them at increased risk of future child abuse.

A number of feasibility studies have been conducted to examine if predictive risk modelling is possible. The main outcome variable used is substantiation, although others were considered by the Ministry of Social Development and may be considered in the future. The first study took place in 2012 and involved the use of data from two main sources: benefit data and Child, Youth and Family data (Vaithianathan, 2012; Vaithianathan et al., 2013). Research into risk factors based on both administrative and purpose-gathered data, as well as the development of actuarial risk assessment tools, is nothing new (Putnam-Hornstein and Needell, 2011; Shlonsky and Wagner, 2005; Baird and Wagner, 2000). However, the use of administrative data to first develop a model, then use it to prospectively risk-score other children, is new: the original authors note that they could find no other use of predictive risk modelling in this way in any journals worldwide, across several languages (Vaithianathan, 2012).

Following the first study published in 2012 (Vaithianathan et al., 2012; Vaithianathan et al., 2013), an application was made to extend the data set to include health and other data – in other words, all births in addition to the Ministry of Social Development data on beneficiaries only – and a further running of the model was completed and reported (Wilson et al., 2015). This study included: births, deaths and marriages data (Department of Internal Affairs); benefit data for the child and other children in the family; Child, Youth and Family data for the child, other children in the family, and their parents or caregivers (relating to their own childhoods); Department of Corrections data on sentences served by parents; and Ministry of Health data on the mother, child and recently born siblings. The latter included administrative markers of transience, mental health...
of the mother, and sibling intentional injury hospitalisations (Wilson et al., 2015, p.510). However, all health data were eventually omitted from the model, surprisingly, ‘as these were found to not improve predictive accuracy’ (Ministry of Social Development unpublished observations, in Wilson et al., 2015, p.511). The second study proceeded with the additional data from births, deaths and marriages from 2000 to 2012 – that is, all births – and sentencing histories of parents. While 12 different algorithms were tested, the most successful one concluded that the three most significant predictors of substantiation were: length of time spent on a benefit; contact with Child, Youth and Family as a child; and the substantiation of other children in the family.

Three uses of the model are currently suggested: first, in early identification, to score every baby at birth and offer those at the greatest level of risk (in the first model, the top decile; in the second, the top 5%) a preventive family-level service; second, as a way to ‘triage’ decision-making at the point of intake into Child, Youth and Family services; and finally, to use in determining neighbourhood-level service needs (Predictive Modelling Working Group, 2014). The use in early identification – that is, at birth – has been put aside at this time due to lack of ‘sufficient certainty’ that the significant risks are ‘outweighed by the potential benefits’ (ibid., p.6). These suggested uses have different implications and issues; however, all rest on the assumed ability of the model to identify particular people as at high risk. But just who are these models identifying? And what is the model able to say about them? A closer examination of the outcome it predicts helps answer these questions.

### Substantiation and incidence: using the decision-making ecology

When building predictive algorithms, an outcome variable must be selected. Ideally this should be a yes/no, or at least a well-defined, variable, and the process that results in that event ‘understood with a high degree of individual accuracy’ (Pierse, 2014, n.p.). Does a person have cancer, or don’t they? Will a person die within five years, or not? For the predictive risk modelling study purposes, the outcome variable chosen was substantiation, meaning a decision that abuse has been investigated and found to have occurred. How accurately the substantiation decision represents true incidence is, therefore, crucial to the effectiveness of the model (Gillingham, 2015). If substantiation is not consistent, or does not represent incidence, then identifying an algorithm to predict it will produce a skewed vision, a warped ‘carve’ as to whom it identifies at each risk decile, as well as which covariates are the most influential predictors of it.

No proxy is perfect, and the study authors have acknowledged that there is bias in the data due to issues related to the notification population (those notified to Child, Youth and Family). Acknowledging the biases in the population notified, however, does not (and cannot) account for variability in substantiation decision-making practices, and the identification of data distance from actual incidence should have an impact on data use. That is, an acknowledgement of the distance between any given proxy and true incidence, combined with the malleable outcome it seeks to predict, should influence the use of that data. In this instance, the distance between the proxy, the outcome and the actual incidence is a further reason to not pursue attempts to identify individuals.

Substantiation data as a reflection of incidence have long been criticised by researchers in the child protection field, including in relation to this study (Fluke, 2009). In terms of predictive accuracy, the percentages of accurate prediction in the Vaithianathan et al. study were: in the top risk decile, 48% accuracy at predicting their substantiation in the system after five years, and in the top two deciles 37% accuracy. 44% of the total substantiated abuse in the time period was found in these top two deciles. In the Wilson et al. (2015) study, the predictive accuracy dropped slightly compared to the Vaithianathan study; of those in the highest risk-scoring 5%, 31.6% had been substantiated by age five years, and 69% had not. In the top risk decile (10%), this accuracy dropped further to just 25.5%.

Several ongoing tests of the predictive risk model are under way: for example, as an aid to decision-making at the point of notification. However, currently, and much to the dismay of the original progenitor, it has not been implemented as a method of ranking all children at birth and offering preventive services based on that score (Vaithianathan and Adams, 2015).
an ill-defined term which incorporates different types with differing causes, using substantiation is unlikely to identify the large amount of abuse that goes undetected, particularly in populations able to avoid detection. Therefore, it is likely to simply ‘reaffirm existing knowledge or biases within the established CYFS framework and may encourage less observation of [some communities]’ (Pierse, 2014, p.2). Other commentators have agreed, noting that far from the claims of it being more ‘objective’ than practitioner decision-making, using substantiation as an outcome variable is likely to reinforce whatever biases exist in the current system (Keddell, 2015b). Shlonksy, one of the more favourable reviewers of the model, notes similar concerns, stating that a major issue is that a ‘prognostic tool perpetuates the current system’ (Shlonsky, n.d., p.2).

Many factors affect the extent to which substantiation can be considered a true indication of actual abuse across the population. These include who is notified to Child, Youth and Family in the first place – that is, the population available to be substantiated – and the substantiation decision itself. Various factors contribute to both these points of population flow through the Child, Youth and Family system and, therefore, the data derived from that system (Office of the Chief Social Worker, 2014). For example, when considering the notification population, families who are subject to more surveillance by potential notifiers tend to be over-represented, particularly those involved in public welfare systems or the justice system, or those in contact with non-governmental organisations (Bradt et al., 2015). This tends to mean over-notification of those who are poor, and, within that group, of those overrepresented among the poor: ethnic minorities, single parents and women (Roberts, 2002).

International research suggests that ethnicity and poverty often affect notification patterns. For example, a study by Mumpower (2010) compared incidence data with those referred (notified) to child protection services in the United States. He found that black children were disproportionately represented in rates of referral, and had higher rates of false positives – that is, those referred but not substantiated. However, he could also show, through the incidence data, that there was a higher rate of false negatives for black children – those who were abused but not notified. The rate of true positives – those referred and then substantiated – is higher for black children, but this was attributed to their higher rate of notification, showing that notifications were less accurate for black children than for children from other racial groups, but also that their apparent higher rate of abuse in child protection statistics was partly attributable to their higher rates of notification. Unfortunately, we have no national incidence study with which to compare child protection data in this way in New Zealand. Cram et al. (2015) completed a comparison of Māori numbers in New Zealand bear this out, with the vast majority of notifications not substantiated despite high needs (as noted earlier, of 146,657 notifications in 2014, 19,623, or 13%, were substantiated), and of those who are, the majority are for the more ambiguous emotional abuse or neglect, with a minority for physical and sexual abuse (5,912 of 19,623, or 30%) (Child, Youth and Family, 2015a). The diversity of this group means predictive models will struggle to identify meaningful risk factors, as those that in fact confer high risk for some types of abuse will be ‘cancelled out’ by those that confer high risk for another, leaving behind potentially spurious or unrelated risk factors, such as contact with administrative systems.

These studies alert us to the greater question of whether the over-representation of poorer people and ethnic minorities in child protection figures represents true differences in rates of abuse or a biased child protection system.
as the ‘risk-bias’ or ‘risk-need’ debate, and has produced an immense range of research into how variables of race and class interact within child protection systems around the world. Too vast to summarise here, this research provides clues about the relationships between these factors and substantiation decisions as well as actual incidence (Jonson-Reid et al., 2009; Dettlaff et al., 2011; Dettlaff et al., 2015; Cram et al., 2015; Drake, Lee and Jonson-Reid, 2009; Bywaters et al., 2014a, 2014b; Williams and Soydan, 2005; Stokes and Schmidt, 2011; Pelton, 2015; Fluke et al., 2010; Ards et al., 2003; Arruabarren and De Paúl, 2012; Wells, Merritt and Briggs, 2009; Wulczyn et al., 2013; Slack, Lee and Berger, 2007; Font, Berger and Slack, 2012). What can reasonably be concluded is that while poverty, particularly, does increase the risk of abuse, due to the increased stressors on poorer parents (particularly if they are operating in resource-poor families and communities), this disproportionality is overstated in child protection system contact, and thus in the data generated from it. The increased contact of poorer people with referrers is an important aspect often glossed over in this debate: the increase in incidence among some populations can only be investigated if it is seen; therefore, increases in child protection statistics can be an effect of poverty despite the appropriateness of the referral to services, and even if the child protection system is not biased.

Practitioner and organisation-specific influences on decision outcomes

In addition to the influence of these broader macro drivers of notifications, substantiation decisions are subject to a range of practitioner, institutional and policy orientation factors, even when affects substantiation decisions, as forcing a range of behaviours and circumstances into the abuse/not abuse dichotomy is often difficult and uncertain in practice.

Substantiation decisions can also relate to pragmatic factors, such as resource availability, that are unrelated to the events or behaviours occurring within the family. Current child welfare decision-making research conceptualises this complex, socially influenced decision-making process as occurring within a nested ‘ecology’. This approach, known as the decision-making ecology (DME) approach, proposes that decisions in child welfare are influenced by individual decision-maker, institutional, contextual and macro-level factors (Baumann et al., 2011; López et al., 2015). Some of those factors, as noted above, include the impact of deprivation, poverty, ethnicity and policy orientation at the macro level, but others include the impact of professional discipline, organisational feedback and cultures, local resources and practitioner education and values. Davidson-Arad and Benbenishty (2014), for example, found that social workers in their study, through a survey of their values, could be divided into pro- and anti-removal (from birth parents) groups. When faced with case vignettes, these value groupings predicted whether the social workers recommended substantiation, removal and length of time in care, regardless of other practitioner demographics.

Enosh and Bayer-Topilsy (2014), in an Israeli study, examined practitioner responses to a series of vignettes. In a factorial survey study they presented the same case, but where some case families had low, some ambiguous and some high levels of objective ‘risk’, some families were of low and some of high socio-economic status, and families were from both the dominant and minority ethnic groups (a 3x2x2 factor survey). Using vignettes removes the impact of higher levels of exposure to child protection services of minority and poorer families, allowing a clearer focus on decision-making post entry. The researchers then elicited information about practitioner risk assessments and decisions. When asked if they could recommend out-of-home placement, no placements were recommended for the no-risk group; 12% of those in the ambiguous group and 56% of the high-risk cases were recommended for removal. Comparing the findings by socio-economic status, they found that recommendations for out-of-home placement for ambiguous risk cases were 20.4% for the low socio-economic group, compared to 3.3% for the moderate-to-high socio-economic status cases. Surprisingly, even in the obviously high-risk group, 87% of low socio-economic status children were recommended for removal, versus 26% of children from higher-income groups. Gillingham (2015) notes that some children are substantiated for reasons other than even a broad definition of abuse, such as behavioural problems or lack of a caregiver. These are just a few of a vast range of studies examining the impact of practitioner variables, apart from an objective and consistent assessment of abuse, on decision outcomes related to individual decision-makers (Cross and Casanueva, 2008; Dettlaff and Rivaux, 2011).

Using vignettes removes the impact of higher levels of exposure to child protection services of minority and poorer families, allowing a clearer focus on decision-making post entry.
In addition to individual decision-maker factors, site-specific organisational variables within child protection services also make a difference to decision outcomes, including differing levels of out-of-home care resources, organisational cultures, thresholds for entry to services or legal intervention (that require a decision of ‘substantiation’) and levels of available non-government services. Bywaters et al. (2014a, 2015) examined the relationship between deprivation and contact with the child protection system in the UK. Not only did they find the anecdotally expected outcome that contact with the child protection system exists across a social gradient, with poorer children overrepresented, but, via spatial modelling, were able to show that an ‘inverse intervention’ law exists, similarly to other health inequalities research (Bywaters et al., 2015). This ‘law’ was expressed in their study by the observation that poorer children in small neighbourhood areas that were surrounded by wealthier areas (local authorities) had vastly higher rates of contact with the child protection system than poorer children living in small neighbourhood areas that were surrounded by similarly deprived larger geographical areas. This suggests that thresholds, neighbourhood resources and practitioner attitudes may differ between neighbourhoods and produce differing notification and substantiation practices, even when deprivation itself remains constant.

In another example, Fluke et al. (2010) tested the influence of organisational factors on decisions, with a view to understanding the over-representation of aboriginal children in Canada in child protection statistics. They utilised the decision-making ecology approach and found, drawing on the national incidence study, which included characteristics of workers and organisations, that the proportion of aboriginal reports to particular site-specific organisations (ranging from 20% to more than 50%) was a key predictor of decisions. Those organisations with high proportions of aboriginal children were more likely to have high removal rates, even when family income and case worker bias were controlled for. They contend that this difference in decision outcomes related solely to the proportions of aboriginal children, suggesting differences in community supports available for aboriginal families in different areas.

Font and Maguire-Jack (2015) also explored agency and geographic factors, case worker attributes and family characteristics in a national survey of well-being sample in the United States. They found that substantiation was ‘strongly influenced by agency factors, particularly constraints on service accessibility. Substantiation is less likely when agencies can provide services to unsubstantiated cases and when collaboration with other social institutions is high’ (Font and Maguire-Jack, 2015, p.70).

### Does this apply to New Zealand? Some clues from descriptive statistics

What do we know about substantiation in New Zealand? While there is no empirical research into decision-making processes and outcomes in the public domain, what is known is this: the substantiation rate as a percentage of notifications ranges widely depending on the office location, suggesting that substantiations may be as subject here to individual and contextual variables as elsewhere. This is highlighted in the predictive risk modelling studies. Of the 13 variables retained after stepwise criteria had been applied in the Wilson et al. study, the Child, Youth and Family site office ranked the fourth most predictive variable, after other children with care and protection history, length of time spent on benefit in the last five years, and caregiver with a care and protection history (Wilson et al., 2015). This dropped to fifth when the most predictive variables across all 16 tested models were considered (Ministry of Social Development, 2014b). The predictive power of the site office suggests differences between office rates of substantiation. While it could be argued that this relates to different levels of need, these variables were only retained if they met the stepwise selection criteria: that is, ‘The significance stay level was set to <0.02, allowing variables to remain in the model only if their significance was less than <0.02 when the effect of other variables was controlled’ (Wilson et al., 2015, p.511). One could expect that if the predictive power of a site office reflected real differences in risk, then it would not be retained once other markers of need or risk had been controlled for. This suggests that it is something about site offices in and of themselves that is influential in substantiation outcomes.

Other clues can be found in descriptive statistics. An examination of substantiation figures shows that in the last year notifications (coming from referrers external to Child, Youth and Family) have remained stable. However, once notifications have entered the Child, Youth and Family system, numbers have dropped at every decision point, flowing through to a significant drop in emotional abuse and neglect substantiations, while other abuse types remain constant (down from 7,992 to 6,326 for emotional abuse, and from 3,510 to 2,695 for neglect for the period of 1 July-31 March 2014 and 2015) (Child Youth and Family, 2015a, 2015b). This suggests that different criteria are being used to substantiate those most contentious and ambiguous categories of emotional abuse and

Policy Quarterly – Volume 12, Issue 2 – May 2016 – Page 51
neglect. A further investigation by region shows that the rates of those notifications judged as ‘requiring further action’ to substantiation varies markedly by region (from 26% to 51%), but remains fairly stable within each region over time (Table 1).

This suggests that substantiation rates may be more influenced by within-region thresholds and practices than by objective similarities between cases. A finer-grained analysis of site offices shows even more diversity of rates of substantiation and notifications, especially when compared to the total child populations covered by site offices. For example, in Clendon in 2014, 9.4% of the total child population of 13,263 were notified to Child, Youth and Family, and of these, 37.6% were substantiated, representing 3.6% of the total child population. In Otara, 4.7% of the total child population were notified, but only 18% of these notifications were substantiated; this was 2% of the total child population. Substantiation rates as a percentage of notifications ranges from 16.2% in Timaru to 54.1% in Taumarunui (Child, Youth and Family, 2014; Ministry of Social Development, personal communication, 2015). These extremely divergent rates of substantiation suggest that factors other than objective similarities at different threshold points are driving substantiation decisions. Shlonsky and Wagner (2005) note that the data relied on to develop risk assessment models can be somewhat ‘noisy’ or variable, noting specifically that: ‘For example, substantiation may be influenced by structural or institutional factors that with the outcome assumes a prominence despite its lack of explanatory or causative power. For example, while previous substantiations were identified as a major predictive variable, subsequent substantiations of the same child or family cannot be considered as statistically comparable to previous substantiations for several reasons. First, flags exist in the Child, Youth and Family system already that alert Child, Youth and Family to new babies born to mothers who have previously had children removed or substantiated, and to the release into the community of offenders with convictions for violence against or abuse of children. Pregnant women with previous children removed, or who were children in care themselves, or who have convictions for offences against children will be monitored by Child, Youth and Family and are likely to have new babies ‘substantiated’ if removal at birth is required. This will be counted as a new substantiation, and in the data will suggest a correlation between the first and subsequent substantiations, yet its occurrence cannot be considered as separate from the earlier substantiation when compared to families with no previous contact with the Child, Youth and Family system. This may seem obvious, but what it means is that abuse occurring in families not monitored to the same degree as those already known to Child, Youth and Family will result in the predictive power of earlier substantiations assuming a statistical weighting not proportionate to the probable actual relationship with future substantiations. This may be further complicated by access to services generated by earlier substantiations (Jonson-Reid et al., 2010; Fuller and Nieto, 2014).

A history of substantiation is also likely to influence current decisions to substantiate for two other reasons, one clinical and one social. Chronicity is an aspect of many clinical definitions of child abuse, so the knowledge of past substantiations may help to form a ‘chronic’ picture in regard to the current notification, making re-substantiation more likely. Secondly, prior substantiation may also make practitioners more risk averse, as it is likely to heighten perceptions of future risk to the child, as well as of the practitioner’s own liability, and lead to a substantiation decision being made (López et al., 2015). For these reasons the identification of earlier substantiation as a predictive variable should be treated with caution, as it is likely to over-identify those with previous substantiations, while not identifying others for whom abuse is occurring. This process is likely to reinforce other aspects of ‘ratcheting’ already in the system: that is, continuing to over-identify certain populations while lowering the portrayed risk of others (Harcourt, 2006). Over time this produces a distortive effect.

Implications for systems design and social work practice
Clearly, many complex factors influence the decision to substantiate, and the...
population notified to child protection services. Together, these patterns result in difficulties when using substantiation data to represent incidence for the purposes of developing individual risk prediction tools. Thus, a model built to predict substantiation must be viewed somewhat cautiously as a particular ‘carve’ of the data which may construct an overlapping, uncertain subset of incidence. Of course, all studies use various proxies and imperfect variables to ‘stand in’ for others. However, the rather extreme issues to do with substantiation in the child welfare context require particularly tentative interpretation, especially when the model is used not simply to describe the risk factors associated with substantiation, but to prospectively predict individuals who may abuse in the future. This sets predictive modelling in this special context apart from predictive models built to predict other types of outcomes. The lack of certainty in regard to substantiation decisions, the socially malleable nature of child abuse and its multiple types all limit its usefulness as a predictive tool – that is, as a way to identify specific individuals, whether for the allocation of preventive services or as an aid in child protection decision-making. In terms of social work practice, statistical predictive variables can assist in practitioner decision-making (via actuarial tools), but need to reflect actual incidence, and should be used in conjunction with a current practitioner assessment of risk (Shlonsky, n.d.; Shlonsky and Wagner, 2005; Munro, 2010; De Bortoli and Dolan, 2014; Platt and Turney, 2014).

Several researchers note the tendency for individualised risk scores to be utilised in negative ways in practice, where actuarial approaches are prioritised over professional judgement. While statistical modellers may understand the tentative nature of statistical prediction or correlation (that is, that just because someone has a heightened risk of a poor outcome, this does not predetermine them to experiencing it), practitioners tend to treat statistical data, especially when stripped of its explanatory variables, as solid knowledge, which can function as a received truth (Keddell, 2015a; Macdonald and Macdonald, 2010; Stevens and Hassett, 2012). The reification of risk scores has implications both for those deemed at high risk – interventions may be more intrusive than warranted – and for those deemed at low risk, who may be passed over for intervention due to a low risk score, when actual family functioning may be extremely abusive. The use of actuarially derived risk scores can also draw practitioners away from considering children and families as existing in ‘complex adaptive systems that must be considered when looking to assess risk in such cases’ (Stevens and Hassett, 2012, p.503), particularly in risk-averse environments increasingly driven by fear of personal liability if a high risk status is viewed as not having been properly ‘acted on’ (Kemshall, 2010; Fleming et al., 2014; Broadhurst et al., 2010). On the other hand, professional judgement can only be properly considered in the real-world contexts in which it may be used, and the development issues to do with substantiation discussed above add heightened caution to its use in practice.

In terms of system design, the current use of the same data set by Treasury may provide a more useful approach that links high-risk groups (of a range of poor outcomes) to areas of high need and multiple risk factors across a community (Crichton, Templeton and Tumen, 2015). A community-level use of the predictive risk model has been suggested, and was also preferred by prominent reviewers. For example, in the Fluke review, Fluke states in response to the suggested use to target preventive services:

> We believe these resources should be prioritised geographically, consistent

**Interventions currently available for this high-risk group are limited. They require tertiary, tailored services able to work with families intensively and supportively, not simply child removal.**
third currently proposed use of the tool is therefore more likely to offer the best response, in a manner commensurate with the limited ability of the tool to identify individual risks accurately.

Another issue for child welfare system design highlighted by this article is that diversity within the notified and substantiated populations calls for different service approaches. It is likely that the population identified by the predictive risk model are already known to services, as the top variables relate to contact with the Child, Youth and Family system (although this would have been worth investigating properly in the now-cancelled prospective study, where children were to be risk-scored at birth, then followed to see if they would gain access to services anyway) (Ministry of Social Development, 2014b). If this is the case, then the problem is not of identification, but how we respond to high-risk families. Interventions currently available for this high-risk group are limited. They require tertiary, tailored services able to work with families intensively and supportively, not simply child removal. When people who have been in care become parents, for example, particular supports are required. As noted above, the broader notified population is a diverse one and tends to be a high-needs group. This wider group requires much better access to universal social protections such as poverty reduction and adequate housing, more ‘hooded’ targeted family support services (those connected to universal services), and community need-based levels of mental health, substance abuse and domestic violence services. As Pierse notes, the real problem is that we need ‘more resources and more interventions’ rather than better ways to identify risky individuals (Pierce, 2014, n.p.; Unicef, 2003; Sethi et al., 2015; Spratt et al., 2014). The Ministry of Social Development has also noted this issue, recommending deferral of the use of predictive risk modelling in early identification until ‘there is capacity to respond appropriately to the children referred’ (Predictive Modelling Working Group, 2014, pp.6-7). Finally, better decision-making research into how substantiations are generated in New Zealand is needed, in order to understand the processes leading to variability in decision outcomes across complex interactions between macro, institutional and individual factors.
